Biometry 2016

Lab 10

Multiple Linear Regression

Filled in Script made by Auriel April 7 2016

```
### Libraries
library(ggplot2) ### regular plotting with ggplot
library(ggfortify) ### this gives us autoplot

## Loading required package: proto

library(MASS) ### this will let us do stepwise regression in an automated fashion
library(ggthemes) # gives us theme_few()
library(car) # gives us durbin.watson()
```

If you want to know what version of R you are using

```
R.version$version.string

## [1] "R version 3.2.3 (2015-12-10)"
```

if you want the citation for your current version of R

```
citation()
```

```

This file is based on a study in which we wished to examine the relationship between physical variables and the density of stonerollers (*Campostoma anomalum*). Stonerollers are small minnows occurring abundantly in Arkansas streams. We measured density of small fish (<80mm) and large fish (>80mm) separately. We sampled fish density in pools and measured physical variables in those same pools.

```
POOL = the pool ID
SITE = the stream name
```

the above two columns are categories, we aren't interested in those

```
SPNUM = species richness
DEPTH = depth in cm
SUBSTRAT = Size of substrate from 1 (sand) to 6 (boulders)
COND = Measure of dissolved ions in the water DO = Dissolved oxygen
HABCOV = Index of available cover
DENSIOM = Measure of canopy openness
MAXDEPTH = Maximum pool depth
STO_SM_DEN = Density of small stonerollers
STO_L_DEN = Density of large stonerollers
```

Run a regression using all predictor variables against small stoneroller density.

Example = lm(data=dat, RESPONSE ~ PREDICTOR1 + PREDICTOR2 + PREDICTOR3)

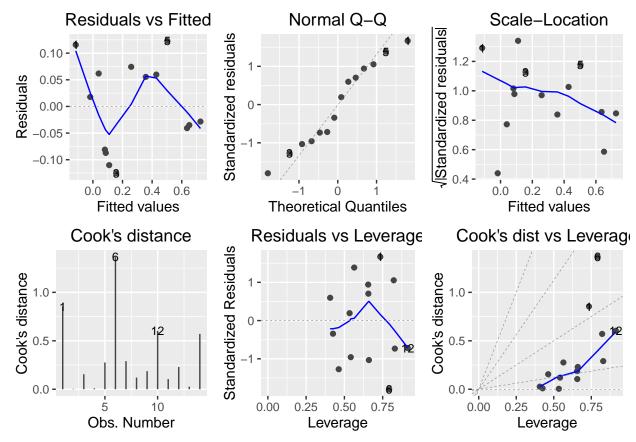

```
model <- lm(data=dat, STO_SM_DEN ~ SPNUM + DEPTH + SUBSTRAT + COND + DO + HABCOV + DENSIOM + MAXDEPTH)
summary(model)</pre>
```

```
##

                                                 0.8378
## ---
```

```
## Signif. codes: 0 '***' 0.001 '**' 0.05 '.' 0.1 ' ' 1
##
## Residual standard error: 0.1345 on 5 degrees of freedom
## (2 observations deleted due to missingness)
## Multiple R-squared: 0.9143, Adjusted R-squared: 0.7771
## F-statistic: 6.665 on 8 and 5 DF, p-value: 0.02573
```

Here we are interested in what coefficients are significant, and what our Multiple R-squared value is. Only Densiom is significant Our Multiple R-Squared is 0.91 which is CRAZY GOOD

autoplot(model, which=1:6, ncol=3, label.size=3)

arguments of autoplot model = the model that you got from lm() above which = the graphs that you want, you don't need to change this ncol = the number of columns, you don't need to change this label.size = this makes the labels a bit bigger, you don't need to change this

What are the assumptions of multiple regression?

Normality Homogeneity of Variance Independence

How can we check for them?

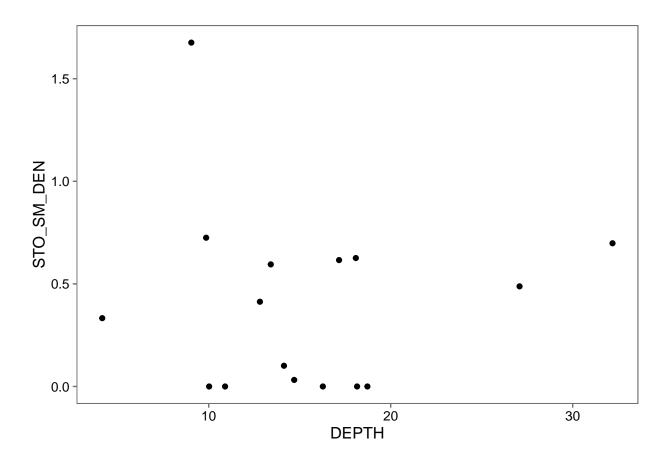

Normality - scatter plots can help, we can also look at the Normal Q-Q plot in the autoplot graph

Homogeneity of variance - scatter plots, and sometimes box plots can help, but since we are dealing with continuous variables box plots are often unhelpful, the residuals vs fitted plot in autoplot is very helpful

Independence - first set is to make sure that the experimental design is set up correctly. You can also run a Durbin's D test to test for independence and look for clumping or anti-clumping in scatter plots

Scatter plot in ggplot

```
ggplot()+geom_point(data=dat, aes(y=STO_SM_DEN, x=DEPTH))+theme_few()
```

You want to look at each predictor variable independently vs the response.

Durbin Watson's D

```
durbinWatsonTest(model)

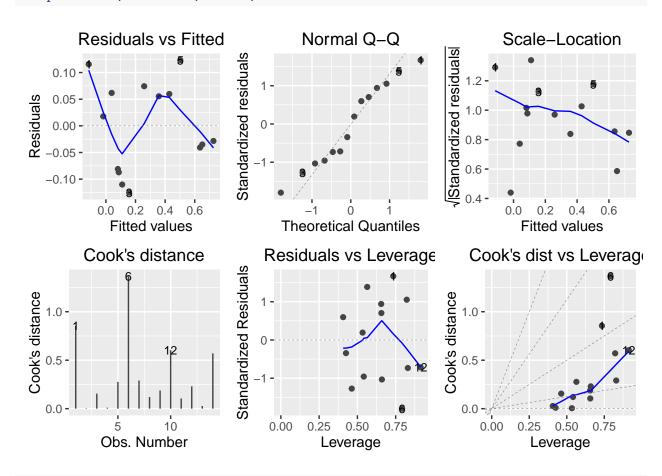

## lag Autocorrelation D-W Statistic p-value
## 1 -0.2385217 2.290096 0.846

## Alternative hypothesis: rho != 0
```

Big p value means that we are good to go. If we had a small p value we would have issues of independence

How do your residuals look?

```
autoplot(model, which=1:6, ncol=3, label.size=3)
```

second column, top graph

```
ss <- summary(model)
ss$r.squared ### r-squared</pre>
```

[1] 0.9142715

```
ss$adj.r.squared ### adjusted r-squared
```

[1] 0.7771058

ss\$coefficients ### regression coefficients

```

```

What does the R2 value represent?

It means how much variation is being explained by the data If your r² is 0.91 that means that your predictors are explaining 91% of the variation in your response variable.

The adjusted R2?

Adjusted R squared is a method of ranking models, the actual value here is not important, you are just interested in if it is bigger or smaller then another model you are considering (like AIC)

How are they calculated?

See your textbook

What do the p values for the regression coefficients mean?

There is a p value for each predictor and that is telling you if you if the relationship for that covariate, is significantly different then zero. These relationships can change depending on the other predictors in the model. So if you are looking at the relationship with DO and you remove MAXDEPTH and rerun the model it could change.

In the ANOVA table, what does the p-value mean?

This value, the p value at the bottom of summary (model) is the significant of the entire model. This may or may not be of interest. Often its the p value of the predictors and the R^2 value that we are really interested in.

Second Data Set

Open the file "multiple regression.csv".

```
setwd("~/Biometry_Materials/20160331_biometry_lab_10_mult_linear_regression")
dat <- read.csv("muliple_regression.csv")</pre>
```

These data are from exclusions of crayfish and fish in the Little Mulberry River.

BIOFILM is the size of the effect of fish and crayfish on stream algal communities (Positive numbers indicate grazing decreased biofilm, negative indicate increases due to grazing).

Check assumptions

(see above)

Perform a step-wise multiple regression predicting BIOFILM from the other variables.

Use a forward and a backward selection procedure in the step-wise regression. Compare the resulting models. Are they similar?

First we will do this the automated way

- pred

```
model <- lm(data = dat, biofilm ~ qdep + pred + cray_density + csr_den_2 + pool_size +

AIC went down!
all p values (except intercept, which we don't really care about, are under 0.15) so this is our final model
```

How do p-values change after each iteration?

Go back and look at the model summaries and check on this

Slope coefficients?

Go back and look at the model summaries and check on this

Return to "sto_den.csv".

```
setwd("~/Biometry_Materials/20160331_biometry_lab_10_mult_linear_regression")
dat <- read.csv("sto_den.csv")</pre>
```

Now I want to know which of the physical variables best explains the variation in density and how much variation the model explains overall.

First check for correlations among independent variables.

```
dat <- dat[!is.na(dat$D0),] # we have two missing DO values, so we are removing those rows

```

Select four candidate models and rank them according to AIC(corrected) values (smaller AIC = better/more parsimonious models).

```
model1 <- lm(data = dat, STO_SM_DEN ~ AREAM2 + COND + DO + HABCOV)
model2 <- lm(data = dat, STO_SM_DEN ~ MAXDEPTH + DO + COND)
model3 <- lm(data = dat, STO_SM_DEN ~ DENSIOM + DO + AREAM2)
model4 <- lm(data = dat, STO_SM_DEN ~ SPNUM + DEPTH + SUBSTRAT + COND + DO +
HABCOV + DENSIOM + MAXDEPTH)</pre>
```

```
AIC(model1)

## [1] 9.850567

AIC(model2)

## [1] 6.834037

AIC(model3)

## [1] 8.700541

AIC(model4)

## [1] -10.84772
```

Do this separately for small and large fish, and then compare the two.

Which variables did you use in your model?

[1] -20.60188

I just strung some together at random, go through and make your own :)

Why?

What does the AIC value take into account?

See text book

For your top model, can you write out the linear model with the beta coefficients?
